RESEARCH MEMORANDUM

NOTES ON DAMPING IN ROLL AND LOAD DISTRIBUTIONS IN ROLL

AT HIGH ANGLES OF ATTACK AND HIGH SUBSONIC SPEED

By Richard E. Kuhn

SUMMARY

Results are presented of an experimental investigation conducted in the Langley high-speed 7- by 10-foot tunnel of the damping-in-roll characteristics of a series of wing plan forms at angles of attack up to 13° and Mach numbers to 0.91. Included also is the spanwise load distribution obtained on one of these wings while rolling.

The results indicate that a large loss in damping occurs at successively lower angles of attack as the Mach number is increased. For swept wings which are subject to pitch-up tendencies, loss of damping occurs at about the angle of attack for pitch-up and those devices which alleviate pitch-up are similarly effective in improving the damping. A procedure is given whereby a satisfactory estimate of the spanwise load distribution can be made if the measured pressure-distribution data in pitch are available.

INTRODUCTION

A considerable amount of effort has been expended in the past on experimental investigations of the damping-in-roll characteristics of various wing plan forms. These investigations have been largely confined to the variation with angle of attack at low Mach numbers (for example, refs. 1 to 7) or the variation with Mach number at low angles of attack (refs. 8 to 20). An indication of the range of these data is presented in figure 1.

Recently an investigation has been conducted in the Langley high-speed 7- by 10-foot tunnel of the characteristics in roll of several wings. Results for an angle-of-attack range from 0° to 13° were obtained at Mach numbers up to 0.91. For one of the wings, pressure distributions were measured during roll. Since some of the results obtained in the investigation are regarded as being very significant, the present paper was prepared in order to summarize some of the more important findings.

~~CONFIDENTIAL~~

COEFFICIENTS AND SYMBOLS

The coefficients and symbols used are defined as follows.

C_L	lift coefficient, perpendicular to relative wind, Lift/qS
C_m	pitching-moment coefficient, Pitching moment/qS \bar{c}
C_l	rolling-moment coefficient, about an axis parallel to the relative wind, Rolling moment/qSb
A	aspect ratio
S	wing area, sq ft (2.25 sq ft for all models)
b	wing span, ft
c	local wing chord, ft
\bar{c}	wing mean aerodynamic chord, ft.
c_{av}	wing average chord, ft
q	dynamic pressure, $\frac{1}{2}\rho V^2$, lb/sq ft
V	free-stream velocity, ft/sec
ρ	air density, slug/cu ft
M	Mach number
α	angle of attack, deg
Λ	sweep angle, deg
$\frac{pb}{2V}$	wing-tip helix angle, radians
p	rolling velocity, radians/sec
c_n	local section normal-force coefficient
y	spanwise distance from plane of symmetry, ft

$$C_{l_p} = \frac{\partial C_l}{\partial \frac{pb}{2V}}$$

~~CONFIDENTIAL~~

MODELS AND TESTS

The models tested included an unswept wing, two swept wings, and one triangular wing each in combination with a common fuselage. The principal geometric characteristics of the wings are given in table I. Ordinates of the fuselage are presented in reference 21. The models were tested on the Langley high-speed 7- by 10-foot tunnel forced-rotation apparatus (ref. 22). The Reynolds number range covered for each of the wings is presented in table I.

A pressure-switch assembly and eight electrical pressure gages were installed in the fuselage to transmit the pressure-distribution data from the rolling wing. The electrical signals from the pressure gages were taken through the slip rings and brushes of the forced-roll apparatus. Because of the limited number of slip rings, it was necessary to use a gang of special pressure switches geared together to connect the pressure orifices in the wing to the electrical gages in successive groups. The pressure data were recorded on a multiple-channel recording galvanometer.

CORRECTIONS

The angle of attack of the model has been corrected for the deflection of the support system under load and for the effects of boundary-induced upwash by the method of reference 23. The blocking corrections which were applied to the dynamic pressure and Mach number were determined by the method of reference 24.

DISCUSSION

Measured Damping Characteristics

The damping-in-roll characteristics of the 45° swept wing (fig. 2) indicate that a serious loss of damping occurs at successively lower angles of attack as the Mach number is increased. At the lower Mach numbers (the data for $M = 0.2$ were obtained from ref. 25), the loss in damping does not occur until after the angle of attack for maximum lift has been considerably exceeded. At the higher Mach numbers the loss in damping occurs at angles of attack below the maximum lift.

Figure 3 shows results for several wings of various plan forms at a Mach number of 0.85. As can be seen, the results indicate poor damping for all the wings in about the same angle-of-attack range. Note also that for the swept plan forms maximum lift has not been reached when this

loss in damping occurs. As would be expected, however, the loss in damping for the unswept wing occurs at an angle of attack slightly above that for the peak in the lift curve.

In the region of instability or very low damping, the variation of rolling moment with rolling velocity was found to be rather erratic, and it is difficult to determine what the effective value of the damping coefficient should be under such conditions. Some typical variations of rolling-moment coefficient C_l with wing-tip helix angle $pb/2V$ are shown in figure 4. At zero angle of attack the variation is quite linear and a stable slope is shown for all wings. These favorable characteristics, however, are maintained only up to an angle of attack of 6° or 8° .

At an angle of attack of 11° the unswept-wing data exhibit a pronounced hysteresis. The data points for the curve were taken in the direction shown by the arrows. It should be remembered, of course, that the angle of attack of 11° for this wing is above the stall at the Mach number selected. For the other wings however maximum lift is obtained at an angle of attack considerably above 11° .

The 32.6° swept wing shows a definite instability over a wide range of rolling velocities. Of the wings tested, this plan form showed the most instability and the instability covered the largest ranges of Mach number and angle of attack.

The 45° swept wing shows a very large reduction in damping, but no hysteresis, at an angle of attack of 11° and a Mach number of 0.85. As was shown in figure 2, a slight instability was obtained at a Mach number of 0.91. This instability occurred only at small values of $pb/2V$.

The 60° triangular wing shows a small region of hysteresis with a stable slope at the higher rolling velocities. These nonlinearities through zero and the hysteresis loops may not be too troublesome with regard to controllability where large rolling velocities are reached; however, they may cause undesirable dynamic stability characteristics. The hysteresis loop would also complicate the design of any automatic stabilizing equipment planned for such an airplane. It might also be expected that the instabilities shown may bear some relation to the wing-dropping problem under maneuvering conditions.

Effect of "Fixes"

Since a loss in damping in roll is known to be strongly associated with tip stalling - which also causes pitch-up for some wing plan forms - tests were made to determine whether devices which are known to alleviate pitch-up would also improve the damping in roll. One such device, a leading-edge notch of $0.02b/2$ width and $0.08c$ depth, located at $0.60b/2$

was tried on the 60° triangular wing and the results are shown in figure 5. This device effectively eliminated both the pitch-up and the damping-in-roll instability within the test Mach number range ($M = 0.7$ to 0.91).

The effect of fences on the 45° swept wing is shown in figure 6. The fences extended the length of the chord and were located at the $0.65b/2$ station. As can be seen, at a Mach number of 0.85 the fences delayed the pitch-up by some 5° and materially improved the damping. However at a Mach number of 0.91 the effectiveness of the fences on either the damping or the pitch-up decreased considerably.

Span-Load Distributions in Roll

In an effort to better understand the forces and distribution of forces contributing to the damping in roll, pressure-distribution measurements during roll were obtained on the 45° sweptback wing. The results at a Mach number of 0.85 and at angles of attack of 0° and 13° are shown in figure 7. Comparisons of the measured and estimated values of the spanwise load coefficient due to roll are given in the upper part of the figure for $\alpha = 0^\circ$. A similar comparison but applied only to the increment due to roll for $\alpha = 13^\circ$ is given in the lower part of the figure. In both cases the agreement between measured and estimated results is quite good. The estimation involved use of measured pressure distributions in pitch, which can be obtained by a relatively simple technique and for which considerable published data are available (refs. 26 and 27). The measurement of pressure distributions during rolling, on the other hand, requires the use of complex equipment. Numerous possibilities for errors or leakage exist and, at best, the precision of the resulting data is only fair.

The procedure for making the estimation is illustrated in figure 8. The local section normal-force curves are presented for spanwise stations of 40, 80, and 95 percent semispan. The increment of angle of attack due to roll at any spanwise station is given by

$$\Delta\alpha = 57.3 \frac{pb}{2V} \frac{y}{b/2} K$$

where K , the correction factor which takes into account the difference in aerodynamic induction for the angle-of-attack and rolling conditions, was derived from reference 28 and is given by the expression

$$K = \frac{2 + \sqrt{4 + \frac{A^2}{\cos^2 \Lambda}}}{4 + \sqrt{16 + \frac{A^2}{\cos^2 \Lambda}}}$$

The variation of the value of K with taper ratio, as well as the spanwise variation of K , has been investigated by using unpublished symmetrical and antisymmetrical loading data computed by the 15-point method of Weissinger (ref. 29). The effects of taper and the spanwise variation of K were found to be small and it therefore appears that the equation given here can be used for all plan forms.

The angle of attack for the wing at zero rolling velocity and for the upgoing and downgoing wing panels at a rolling velocity equivalent to $\frac{pb}{2V} = 0.06$ are indicated in figure 8. The increment of spanwise load coefficient due to rolling is merely the difference in section normal-force coefficient (multiplied by the appropriate chord ratio) between the angle of attack for $\frac{pb}{2V} = 0$ and $\frac{pb}{2V} = 0.06$, as indicated in figure 8.

As is shown in figure 7 this procedure yields results that are in good agreement at both low and high angles of attack. Because of the difficulties of obtaining pressures in roll, it is felt that an estimation procedure of the type outlined may be the more practical approach in most instances.

CONCLUDING REMARKS

An investigation of the damping-in-roll characteristics of four wings at Mach numbers up to 0.91 and at angles of attack up to 13° indicates that a serious loss in damping generally occurs at successively lower angles of attack as the Mach number is increased. For swept wings which are subject to pitch-up tendencies, loss of damping in roll normally occurs at about the angle of attack for pitch-up and those devices which alleviate pitch-up are similarly effective in improving the damping in roll. Also, the increment of span load distribution due to roll can be satisfactorily estimated if measured pressure-distribution data in pitch are available.
